Abstract. The Laser Interferometric Space Antenna (LISA) will observe supermassive black hole binary mergers with amplitude signal-to-noise ratio of several thousands. We investigate the extent to which such observations afford high-precision tests of Einstein's gravity. We show that LISA provides a unique opportunity to probe the non-linear structure of post-Newtonian theory both in the context of general relativity and its alternatives.

In a black hole binary, as the two holes orbit about their centre-of-mass, the energy and angular momentum from the system is dissipated into gravitational radiation. The radiation back-reaction force causes the two bodies to gradually spiral in towards each other, resulting in a strong burst of radiation just before they merge to form a single black hole. The radiation emitted at the end of the binary evolution is the primary target of both the ground- and space-based interferometric gravitational wave (GW) antennas [1]. It has become necessary to gain an accurate understanding of the late-time evolution of binaries in order to help data analysts in detecting the signal and measuring the parameters by fitting the observed signal with that expected from general relativity.

In General Theory of Relativity there is no exact solution to the two-body problem. In the absence of an exact solution (analytical or numerical) theorists have resorted to an approximate solution to the problem using post-Newtonian (PN) theory. Briefly, the programme of PN theory is the following. Let us consider a binary consisting of two non-spinning black holes of masses m_1 and m_2 (total mass $M = m_1 + m_2$, symmetric mass ratio $\eta = m_1 m_2 / M^2$) separated by an orbital (Schwarzschild coordinate) distance $r(t)$. Post-Newtonian theory expresses the relevant physical quantities as a series in the ‘small’ velocity parameter $\epsilon = v/c \equiv \sqrt{GM/rc^2}$. For a system consisting of non-spinning black holes the only relevant quantities are the (specific) binding energy E and the GW flux $\mathcal{F}$, which are obtained as perturbative expansions in v . (Following the standard convention, in units where $G = c = 1$, v^n corresponds to a term of order $\frac{n}{2}$ -PN.) Currently, these expansions are known to order v^7 or 3.5PN [2, 3]:

$$E = -\frac{1}{2}\eta v^2 \sum_{k=0}^3 E_k v^{2k}, \quad \mathcal{F} = \frac{32}{5}\eta^2 v^{10} \sum_{k=0}^7 \mathcal{F}_k v^k, \quad (1)$$

where E_k and $\mathcal{F}_k$ are the PN expansion coefficients that are all functions of the mass ratio η .

In the *adiabatic approximation* one then uses the energy balance equation, $-dE/dt = \mathcal{F}$, to compute the evolution of the orbital phase $\varphi(t)$ using the following coupled ordinary differential equations:

$$\frac{d\varphi}{dt} = \omega = \frac{v^3}{M}, \quad \frac{dv}{dt} = \frac{dE/dt}{dE/dv} = \frac{-\mathcal{F}}{E'(v)}, \quad (2)$$

where $E'(v) \equiv dE/dv$. The phase $\Phi(t)$ of the emitted radiation at dominant order is simply twice the orbital phase: $\Phi(t) = 2\varphi(t)$.

The phasing formula obtained by solving the above differential equations includes different PN terms arising from nonlinear multipole interactions as the wave propagates from the source’s near-zone to the far-zone [4]. The 1.5PN and 2.5PN term arise solely due to the interaction of the Arnowitt-Deser-Misner (ADM) mass of the source and the quadrupole moment. It is physically due to the scattering of quadrupolar waves off the Schwarzschild curvature generated by the source and is referred to as the gravitational wave tail. The 3PN term includes, in addition to the terms at the retarded time, more interestingly the cubic nonlinear interactions due to the scattering of the wave tails by

the ADM mass energy of the spacetime. The observational tests of these PN terms in effect test the nonlinear structure of Einstein's gravity.

In the restricted PN approximation (so called because one keeps only PN corrections to the phase of the radiation but neglects amplitude), the response of an interferometric antenna to the incident radiation from a source at a luminosity distance D_L is

$$h(t) = \frac{4\mathcal{C}\mathcal{M}}{D_L} [\pi\mathcal{M}F(t)]^{2/3} \cos \Phi(t), \quad (3)$$

where $\mathcal{M} = \eta^{3/5}M$ is the so-called *chirp mass* of the system, $F(t) \equiv \frac{1}{2\pi} \frac{d\Phi(t)}{dt}$ is the instantaneous frequency of the radiation, $0 \leq \mathcal{C} \leq 1$ is a dimensionless geometric factor that depends on the relative orientation of the binary and the detector and its average over all orientations is $\bar{\mathcal{C}} = 2/5$. The importance of including PN corrections in the phase, and neglecting them in the amplitude, was realized quite early on [5] and has led to a lot of simplification of the data analysis problem. For the tests proposed in this Letter it may eventually be necessary to incorporate these amplitude corrections [6]. For the sake of simplicity, however, we have refrained from doing so in this work.

For our purposes it will be useful to work with the Fourier transform $\tilde{h}(f) \equiv \int_{-\infty}^{\infty} h(t) \exp(2\pi i f t) dt$ of the above signal. Using the stationary phase approximation it has been shown that [1, 7]

$$\tilde{h}(f) = \mathcal{A} f^{-7/6} \exp \left[i\Psi(f) + i\frac{\pi}{4} \right], \quad (4)$$

with the Fourier amplitude $\mathcal{A}$ and phase $\Psi(f)$ given by

$$\begin{aligned} \mathcal{A} &= \frac{\mathcal{C}}{D_L \pi^{2/3}} \sqrt{\frac{5}{24}} \mathcal{M}^{5/6}, \\ \Psi(f) &= 2\pi f t_C + \Phi_C + \sum_k \psi_k f^{(k-5)/3}. \end{aligned} \quad (5)$$

Here t_C and Φ_C are the fiducial epoch of merger and the phase of the signal at that epoch. The coefficients in the PN expansion of the Fourier phase are given by [8, 9, 10]:

$$\psi_k = \frac{3}{128\eta} (\pi M)^{(k-5)/3} \alpha_k, \quad (6)$$

$$\begin{aligned} \alpha_0 &= 1, \quad \alpha_1 = 0, \quad \alpha_2 = \frac{3715}{756} + \frac{55}{9}\eta, \quad \alpha_3 = -16\pi, \\ \alpha_4 &= \frac{15293365}{508032} + \frac{27145}{504}\eta + \frac{3085}{72}\eta^2, \\ \alpha_5 &= \pi \left(\frac{38645}{756} - \frac{65}{9}\eta \right) [1 + \ln(6^{3/2}\pi M f)] \\ \alpha_6 &= \frac{11583231236531}{4694215680} - \frac{640}{3}\pi^2 - \frac{6848}{21}\gamma \\ &\quad + \left(-\frac{15737765635}{3048192} + \frac{2255}{12}\pi^2 \right) \eta \\ &\quad + \frac{76055}{1728}\eta^2 - \frac{127825}{1296}\eta^3 - \frac{6848}{63} \ln(64\pi M f), \\ \alpha_7 &= \pi \left(\frac{77096675}{254016} + \frac{378515}{1512}\eta - \frac{74045}{756}\eta^2 \right). \end{aligned} \quad (7)$$

Unlike the other parameters ψ_k , $k \neq 5, 6$, which depend only on the masses of the system and are thus constants, the parameters ψ_5 and ψ_6 are *not* constants and have some $\log f$ -dependence. We treat the log-terms as constants with the justification that the log-dependence on the frequency is weak in the relevant bandwidth. Another possible choice is where the coefficients of the log-terms are treated as additional signal parameters. This choice, indeed, increases the dimensionality of the parameter space making the Fisher matrix highly ill-conditioned and we do not discuss it here.

Post-Newtonian theory has been highly successful in explaining the decay of the orbital period in binary pulsars and in confirming the emission of gravitational radiation by these relativistic systems (cf. [11] and references therein). Nevertheless, the binary pulsar radio observations do not test PN theory to a high order. This is because the typical velocity in the most relativistic of binary pulsars is $v \sim 3 \times 10^{-3}$, which is not large enough for higher order terms to be important.

GW observation of the coalescence of binary black holes (BBH) will provide a unique opportunity to test the PN theory to very high orders. This is because the velocities in the system, close to the merger, could be as high as $v \simeq 0.2-0.4$, making the highest order known PN term $10^{12}-10^{14}$ times more important for GW observations than for radio binary pulsars and several tests of general relativity have already been proposed by various authors [12, 13, 14]. We shall show in this Letter that the brightest events that can be expected in the space-based Laser Interferometer Space Antenna (LISA) will test all the PN terms computed so far.

Our proposal to test the PN theory is the following: let us suppose we have a GW event with a high signal-to-noise ratio (SNR), say more than 1,000. Once an event is identified we suggest to fit the data to a signal wherein each term in the PN expansion is treated as an independent parameter. More precisely, instead of fitting the detector output with a signal that depends on only the two mass parameters, we could fit it with the same signal but by treating all the ψ_k 's as independent. For example, if we want to test the PN theory to order v^4 then we should use a four-dimensional grid of templates consisting of $\{\psi_0, \psi_2, \psi_3, \psi_4\}$ rather than the two-dimensional one that is used in the detection problem. This higher-dimensional fitting of the data with our model would measure each of the PN coefficients independently of the others. In Einstein's theory, for the case of nonspinning binaries, each of the ψ_k 's has a specific relationship to the masses, $\psi_k = \psi_k(m_1, m_2)$, whereas in a different theory of gravity (for example, a theory in which the graviton has non-zero mass) the relationship will be different and might involve new parameters. Thus, the measured ψ_k 's could be interpreted, in principle, in the context of different theories of gravitation.

In the case of general relativity we know that the ψ_k 's are given in terms of the masses by Eqs. (6) and (7). If general relativity (or, more precisely, the PN theory that approximates general relativity) correctly describes the dynamics of the system then the parameters must be consistent with each other within their respective error bars. One way to check the consistency would be to invert the relationships between the ψ_k 's and the masses to obtain $m_2 = m_2^k(m_1, \psi_k)$, and plot m_2 as a function of m_1 for various

ψ_k 's, and see if they all intersect at a common point. If they do, then the theory is correct to within the measurement errors, if not, the theory is in trouble. In addition to the PN theory we could also test other approximants, such as the P-approximant [15] or the effective one-body approximation [16] that have been proposed as alternatives to the orbital dynamics of binary inspirals as also numerical relativity predictions.

Although these tests are in principle possible, an important question is whether the various PN coefficients can really be measured accurately enough for the test to be meaningful. We already know that a simpler test proposed in Ref. [12], in the context of ground based detectors, requires events with SNRs in excess of 25. The generalized tests proposed in this Letter would require much stronger signals, SNRs of 100 to test lower-order terms and in excess of 1,000 to test all terms currently known. Initial ground-based interferometers are unlikely to observe events with such large SNRs. While some of these tests might be possible with advanced detectors, a supermassive BBH merger in LISA is our best bet.

To test an approximation it should be possible to measure the various PN coefficients with a good accuracy. We shall require that the relative error in the measurement of a parameter be less than 100%, i.e. $\Delta\psi_k/\psi_k \leq 1$, where $\Delta\psi_k$ is the error in the estimation of the parameter ψ_k , in order that its presence is tested with confidence.

Next, we will work out the accuracy with which we can measure the various parameters in the standard PN theory. Given a signal $\tilde{h}(f; \theta_k)$ that depends on the parameters θ_k the information matrix g_{ab} is given by

$$g_{km} = \langle h_k, h_m \rangle, \quad (8)$$

where $h_m = \partial h(f; \theta_k)/\partial \theta_m$, and for any two functions a and b their scalar product $\langle a, b \rangle$ is defined as:

$$\langle a, b \rangle \equiv 2 \int_0^\infty \left[\tilde{a}(f) \tilde{b}^*(f) + \tilde{a}^*(f) \tilde{b}(f) \right] \frac{df}{S_h(f)}, \quad (9)$$

with $\tilde{a}(f)$ being the Fourier transform of $a(t)$. The quantity $S_h(f)$ is the one-sided noise power spectral density (PSD) of the detector with units of Hz^{-1} ; it is the only characteristic of the detector that enters the calculation of the errors in the estimation of parameters.

The variance-covariance matrix C_{ab} is nothing but the inverse of the information matrix, $C_{ab} = g_{ab}^{-1}$. The diagonal components C_{kk} are the variances in the parameters θ_k . $C_{km}/\sqrt{C_{kk}C_{mm}}$, $k \neq m$, are the correlation coefficients between parameters θ_k and θ_m , taking on values in the range $[-1, +1]$.

For the binary system in question defining a new parameter vector $\boldsymbol{\theta} \equiv \{t_C, \Phi_C, \psi_0, \psi_2, \dots, \psi_7\}$ one finds

$$g_{ab} = 4\mathcal{A}^2 \int_{f_s}^{f_{\text{iso}}} f_{ab} f^{-7/3} \frac{df}{S_h(f)},$$

$$f_{ab} \equiv \frac{\partial \Psi(f; \boldsymbol{\theta})}{\partial \theta_a} \frac{\partial \Psi(f; \boldsymbol{\theta})}{\partial \theta_b}. \quad (10)$$

Note that we have now introduced specific values for the limits in the integration: f_s is simply the lower frequency cutoff chosen such that the loss in the SNR due to this choice is negligible compared to the choice $f_s = 0$ and f_{iso} is the frequency of the radiation at the last stable orbit of the system which we assume to be the value given in the test mass approximation, namely $f_{\text{iso}} = 1/(6^{3/2}\pi M)$. Using the Fourier phase given in Eq. (5) it is straightforward to compute f_{ab} :

$$\begin{bmatrix} 4\pi^2 x^6 & 2\pi x^3 & 2\pi x^{-2} & 2\pi & 2\pi x & 2\pi x^2 & 2\pi x^4 & 2\pi x^5 \\ 2\pi x^3 & 1 & x^{-5} & x^{-3} & x^{-2} & x^{-1} & x & x^2 \\ 2\pi x^{-2} & x^{-5} & x^{-10} & x^{-8} & x^{-7} & x^{-6} & x^{-4} & x^{-3} \\ 2\pi & x^{-3} & x^{-8} & x^{-6} & x^{-5} & x^{-4} & x^{-2} & x^{-1} \\ 2\pi x & x^{-2} & x^{-7} & x^{-5} & x^{-4} & x^{-3} & x^{-1} & 1 \\ 2\pi x^2 & x^{-1} & x^{-6} & x^{-4} & x^{-3} & x^{-2} & 1 & x \\ 2\pi x^4 & x & x^{-4} & x^{-2} & x^{-1} & 1 & x^2 & x^3 \\ 2\pi x^5 & x^2 & x^{-3} & x^{-1} & 1 & x & x^3 & x^4 \end{bmatrix}$$

where $x = f^{1/3}$. We see that the information matrix will involve moments of the noise spectrum of the form $\int_0^\infty f^{-j/3} \frac{df}{S_h(f)}$, where j runs from 1 to 17. The elements of the information matrix, therefore, take on values in a very large range leading to a highly ill-conditioned matrix. Extreme caution should be exercised in computing the moments, else it is easy to end up with values in the covariance matrix that are negative, and even imaginary, while we know that the covariance matrix should be real. We have verified our results using three different methods for numerical integration and found that they differed from one other by no more than 10 %.

We assumed that LISA consists of only one interferometer with sensitivity as in Ref. [17, 18, 14] and the binary consists of two black holes of equal masses in quasi-circular orbit and observed for one year before merger. Fig. 1 plots the error in the various parameters ψ_k as a function of the total mass for optimally oriented supermassive BBH mergers at a distance of $D_L = 3$ Gpc. We shall be interested in binaries with their

Figure 1. Errors in the measurement of the PN coefficients. The sources are optimally oriented supermassive BBH located at a luminosity distance of $D_L = 3$ Gpc.

total mass in the range $2 \times 10^4 M_\odot - 2 \times 10^7 M_\odot$. At 3 Gpc such sources would produce SNR in the range 1,000-6,000. From Fig. 1, wherein the log-terms are treated as constants, it is clear that in the mass range $10^5 - 10^6$, fractional errors associated with most of the parameters are less than 1. Thus, LISA will provide a unique opportunity to test the PN and related approximations to a high degree of accuracy.

Fig. 2 illustrates how one might test for the consistency of the individual masses for the specific system of the merger of black holes each of mass $10^{5.1} M_\odot$. We have chosen a system that gives the lowest errors in different parameters (cf. Fig 1) and assumed that the source is at a distance of 1 Gpc. For each parameter ψ_k we have plotted the region enclosed by the boundaries $\psi_k + \Delta\psi_k$ and $\psi_k - \Delta\psi_k$, where $\Delta\psi_k$ is the one-sigma error in the estimation of ψ_k [‡]. The higher order ψ_k 's will have to enclose the region determined by, say ψ_0 and ψ_2 . This will be a stringent test for the various parameters and will be a powerful test if LISA sees a merger event with a high SNR of $\sim 10^4$. For binaries that merge within 1 Gpc the test would confirm the values of the known PN coefficients to within a fractional accuracy of ~ 1 .

It would be interesting to ask whether the proposed tests can, in principle, distinguish general relativity (GR) from, say a theory that also includes a massive graviton [13]. In this theory the 1PN parameter ψ_2 is different from that in GR. Remarkably, we find that an year's worth of observation of BBH mergers in the mass range $2 \times 10^4 - 2 \times 10^7 M_\odot$ should be sufficient to discriminate GR from a massive graviton theory provided the Compton wavelength of graviton $\lambda_g \leq 5.5 \times 10^{14} - 3.8 \times 10^{15}$ kms. These limits make the simplifying assumption of neglecting the as yet uncomputed

[‡] Since ψ_6 has only log-dependence on the frequency, we have treated it to be a constant and have chosen $f = f_{\text{iso}}$ in ψ_6 in our calculations. Other choices of the frequency would alter the shape of the contour corresponding to ψ_6 in the $m_1 - m_2$ plane, and our choice corresponds to the one for which ψ_6 will be the largest as the signal sweeps the detector band and leads to smallest errors. Finally, there is no test corresponding to ψ_5 in Fig 1 and 2 as a constant ψ_5 gets absorbed into a redefinition of the coalescence phase Φ_C .

Figure 2. The m_1 - m_2 plane plot for different ψ_k 's for the merger of a BBH of $2 \times 10^{5.1} M_\odot$, at a luminosity distance of 1Gpc.

higher PN order corrections to GW phase in the massive graviton case. (See also [19] for a discussion regarding the extent to which GW observations can critically distinguish between different theories of gravitation in comparison to the binary pulsar tests.)

In the present work we have dealt with only non-spinning binaries. The spin parameters, β from spin-orbit coupling at 1.5PN and σ from spin-spin coupling at 2PN, are assumed to be less significant for these equal mass systems. For the unequal mass case the spin effects are expected to be more important. Orbital eccentricity, which might introduce systematic effects in these tests, has not been included as we have restricted our analysis to binaries in quasi-circular orbits. Massive graviton theories can be tested since they lead to a phasing formula that is structurally similar to general relativity but with terms modified due to the propagation delay. Alternative theories of gravity, such as the Brans-Dicke theory, where the PN structure of the phasing is different due to the presence of dipolar radiation, may also be tested by a straightforward extension of the above proposal. These and other issues will be investigated in future.
